Summary. The effects of induced hypothalamic hyperphagia and forced-feeding were studied in 30 geese of the Landes breed. They were housed in individual cages under a dark-light cycle of 12 hrs light-12 hrs darkness. Eleven geese with ventromedian hypothalamic (VMH) lesions and 8 controls were fed *ad libitum*. A third lot of 11 force-fed animals was pair-fed with the operated geese. The study lasted 4 weeks after an adaptation period to the new environmental conditions. The daily food intake of the geese and their weekly liveweight gain were monitored. After VMH lesions, the mean food intake of the geese increased by 169 p. 100 so that after each treatment their liveweight increased and they became obese ($P < 0.001$). The tissue distribution of the group with lesions showed a higher amount of subcutaneous fat ($P < 0.05$), while the mesenteric fat ($P < 0.05$) was more abundant after forced-feeding. The liver weight was much higher in all cases ; its increment reached 311 p. 100 in geese with VMH lesions and 193 p. 100 in the force-fed. However, those values were too low when compared to the means obtained by traditional forced-feeding. Hyperphagia in the geese was very marked as compared to that in rats, but it was insufficient to produce a considerable hepatic steatosis.

Introduction.

The nervous system, and especially the hypothalamus, plays a large role in the control of food intake. It also intervenes in the mobilization, utilization and storage of fats in the organism. The ventromedian hypothalamic nuclei (VMH) are implicated in the regulation of these processes. As early as 1940, Hetherington and Ranson showed that bilateral electrolytic lesions of the VMH in laboratory rats caused some behavioral deviations ; one of these was increased food intake with the development of obesity.

While much work has been done in rats, research in birds is more recent and rare. It has been shown that birds (Feldman *et al.*, 1973), and particularly geese (Auffray and Blum, 1970), have the same symptoms after destruction of the mediobasal hypothalamic area. Such physiological modifications as functional castration, hyperphagia, rapid liveweight gain, marked obesity and the characteristic appearance of a dynamic then a static phase and hepatic steatosis have been reported. In the chicken, Lepkovsky and Yasuda (1966) emphasized the effect of mediobasal hypothalamic lesions on growth and body composition. Snapir *et al.* (1976) showed the involvement of the hypothalamus and the septal area in the control of food intake and liveweight in geese.

The forced-feeding technique is traditionally used to obtain fatty liver (Fleuret, 1953 ; Leclercq *et al.*, 1968), but is also produces lipid accumulation in storage tissues (Labie and Tournut, 1970). Thus, hyperphagia induced by lesions or by cramming causes marked changes in lipid metabolisms. Considering the economic importance of forced-feeding and the potentialities of the practical application of induced hyperphagia, and since there are no data in the literature, we were motivated to compare the effects of each of these treatments on the development of some tissues and organs in the goose.

Material and methods.

Animals and food intake. — Sixty-four 6 to 9-month old geese of the Landes breed from the Artiguères Experimental Station were used. They were put into individual cages under a 12/12 light-dark cycle and fed a semi-liquid diet (1 part of meal to 2 of water) *ad libitum* containing 18 p. 100 proteins and 9 p. 100 lipids, supplying 4 742 calories per kg of dry matter.

The geese were divided into three groups, including 8 controls, 28 birds with VMH lesions and 28 force-fed birds. The amount of dry food given to the force-fed in 3 meals every 24 hrs, as in traditional cramming, was based on the quantity of dry food ingested spontaneously in 24 hrs by the hyperphagic geese 2 days before.

Four of the traditionally force-fed geese died as a result of cramming accidents (choking). Thirteen of the hyperphagics were discarded because the VMH had been

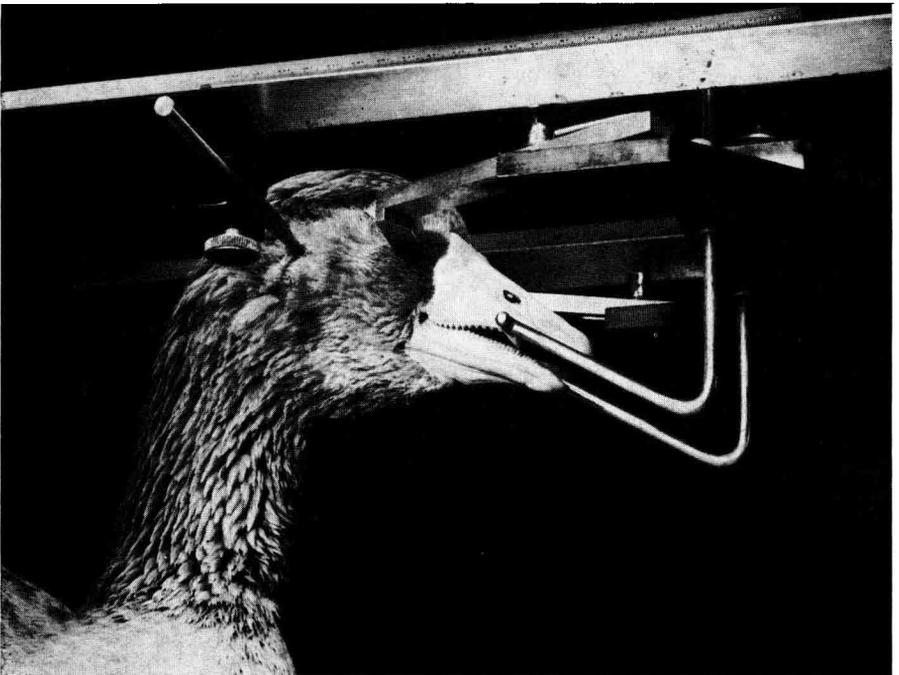

PHOTO 1. — Goose in the stereotaxic apparatus modified by Auffray.

imperfectly destroyed. Due to pair-feeding, 17 geese were discarded in each lot treated, leaving 11 animals per group.

Destruction of VMH nuclei. — After being anesthetized with sodium thiopental (1 : 60 solution in distilled water), given by continuous perfusion in the wing vein, the geese were placed in a modified Horsley and Clark stereotaxic apparatus especially adapted to that species (photo 1). The head was fixed by the auditory meatus, the zygomatic arch and the beak.

The exact localization of the electrode in relation to bone reference points was checked by X-ray, thus reducing errors due to the large individual variations of the stereotaxic coordinates of the nervous system structures studied.

The VMH was destroyed by sending a continuous anodic 3 mA current for 30 sec through a steel electrode 7 μ m in diameter with 1 mm of its end stripped.

Collection of data. — After the animals had been adapted to the environmental conditions, food intake was monitored for 5 days before surgery and for 4 weeks afterwards ; liveweight was recorded every week.

At the end of the 4 weeks the birds were killed by decapitation. The heads with the VMH lesions were perfused through the carotid arteries with a 10 p. 100 formic aldehyde solution. The brain thus fixed *in situ* was removed to localize the destruction and its extent. Serial frontal frozen sections of 100 μ were prepared and stained with thionine (Nissl bodies). After examination of the histological sections, only those animals with bilateral and symmetrical VMH lesions were selected for study (photo 2).

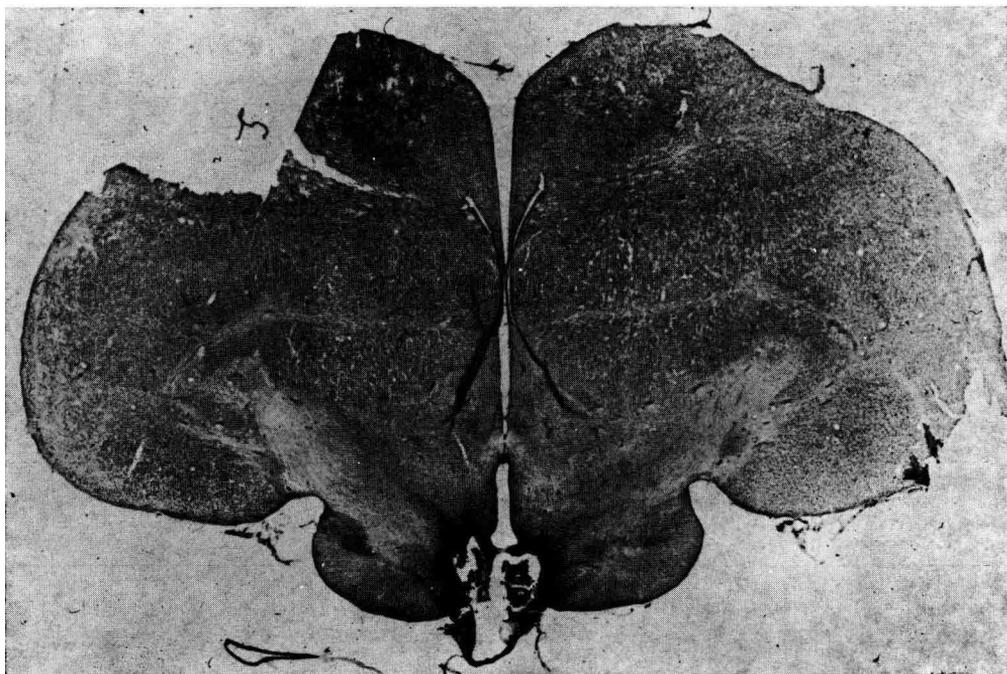

PHOTO 2. — Frontal section of the goose diencephalon showing the site of VMH hypothalamic lesions.

The carcasses were dissected so as to separate the external fat (skin + subcutaneous) and internal fat (abdominal + mesenteric), muscles and bones; these different fractions as well as the intestine without the cloaca, were weighed. The fresh weight of the emptied intestine, the liver without gall bladder, the heart drained of blood, the pancreas, thyroid and adrenal glands was also determined. To maintain an homogeneity in the expression of the data and for purposes of comparison with already existent findings, the results of this study are given in percentages of liveweight. The data were compared by analysis of variance (F-test).

Results.

1. *Food intake and liveweight gain.* — Figure 1 shows that the amounts of food ingested daily increased immediately after VMH destruction. The dynamic phase continued up to day 15. Daily food intake then decreased gradually. Table 1 shows that the geese

NS Non-significant.

with VMH lesions were clearly hyperphagic since their mean food intake increased by 169 p. 100.

The liveweight gain pattern was similar in both groups of treated animals (fig. 2). The curves showed no statistical differences during the 30 experimental days. On the other hand, at the end of that period, liveweight appeared to be significantly higher than in the control groups, but of the same order of magnitude after each treatment.

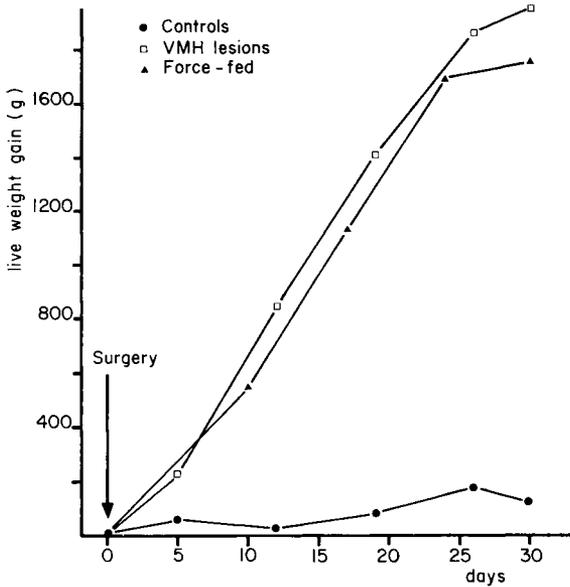

FIG. 2. — Cumulated liveweight gain patterns of control, VMH-hyperphagic and force-fed geese.

*** P < 0.001, * P < 0.05, NS Non-significant.

2. *Effect of treatment on tissue distribution.* — Table 2 presents the whole of the weights of the different body fractions. The total quantity of fat increased in operated and force-fed geese by 35 and 29 p. 100, respectively, as compared to the control lot. Treatment effect on external fat was more evident because significant increases were found (34 p. 100 after lesion and 18 p. 100 after forced-feeding). On the other hand, forced-feeding enhanced internal fat development which increased by 53 p. 100 as against 40 p. 100 in lesioned birds when compared to the control group.

The percentages of muscle and bone in relation to liveweight were significantly lower in operated geese, thus showing a certain stability of the absolute value.

3. *Effect of treatment on organ weights.* — Ponderal liver gain was considerable during the experiment : 193 p. 100 in force-fed birds and 311 p. 100 in operated ones. The weight of the intestine, heart and pancreas did not vary in the three lots. On the other hand, thyroid weight decreased in the force-fed animals, while the adrenals weighed less after VMH lesion.

Discussion.

Electrolytic lesion of the goose ventromedian hypothalamus induced hyperphagia, thus causing considerable obesity. This hyperphagia seemed much more marked than in the rat given the same treatment (Brobeck, Tepperman and Long, 1942, 1943). In the chicken, however, Lepkovsky and Yasuda (1966) mentioned hyperphagia when there was none since the chickens became obese without overeating. These authors believed that, as in the rat (Kennedy, 1953), this ponderal gain was essentially the result of an increase in body lipid depots ; our results confirm this. Indeed, after treatment, the total amount of body fat was clearly higher (P < 0.001).

A difference in the treatments is evidenced by the difference in cover fat, which was found in increasing amounts in the control, force-fed and operated groups, respectively. However, the percentage of internal, and especially mesenteric, fat was higher at the end of forced-feeding since it reached 29 p. 100 as against 14 p. 100 in operated geese. It is to be wondered if these differences would have occurred or developed if the experimental time-course had been varied. As observed in the obese chicken with hypothalamic lesions (Lepkovsky and Yasuda, 1966), the carcass lipid distribution in our study was regular since the external fat/internal fat ratio did not vary significantly among the three groups.

According to Snapir (1976), ponderal liver gain after VMH lesion is mainly due to the large augmentation of hepatic fats which is identical to that found after forced-feeding. This development seems normal since the bird liver is considered as the principal site of lipogenesis (O'Hea and Leveille, 1969). Therefore, any overeating should cause a quantitative increase of hepatic fat, and especially in the present study which used geese genetically selected for their ability to produce fatty livers. There did not seem to be a correlation between the weight of the liver and of the different fats, except for the external fat of the lesioned lot ($r = 0.57$; $P < 0.1$). However, contrary to the data of Snapir (1976), liver weight was correlated to mean daily food intake ($r = 0.68$; $P < 0.01$). This relation disappeared after forced-feeding and liver weight became closely related to that of the internal fat ($r = 0.84$; $P < 0.001$) as Nir, Perek and Katz (1972) already reported. Liver weight was more highly correlated to live-weight at slaughter in operated ($r = 0.80$; $P < 0.01$) than in force-fed ($r = 0.57$; $P < 0.1$) geese. Thus, lesioned birds fed *ad libitum* showed a relatively extensive liver development with fat accumulation ; the fraction released into the blood was more massively stored in subcutaneous fat. On the other hand, in geese force-fed 3 times a day, a part of the hepatic stores was preferentially evacuated towards the abdomen.

It can be supposed that for the same food intake level, adiposity develops differently depending on the feeding procedure. Snapir *et al.* (1976) studying the goose and other authors reporting on the rat, suggested that immediate changes in digestibility and digestive transit rhythm might occur after VMH lesion. Moreover, as in the rat, there may be divergences in the assimilation and utilization of nutriments as well as in lipogenesis with a quantitatively high increase of fat in the adipose tissues. Consequently, the lesions would appear to cause more anabolism than would forced-feeding, although the metabolism seemed to be modified in both cases.

The fatty livers obtained by electrocoagulation, while not significantly different in weight from those produced by forced-feeding, were still clearly smaller (312 g) than the livers obtained by the traditional method (660 g). The mean amounts of food ingested after VMH lesions (471 g/day) were still too low to induce the formation of fatty liver with cramming (716 g/day for 21 days). Immediately after surgery, the food intake pattern of our lesioned birds increased up to day 15 and then decreased until the end of the experiment. According to Lepkovsky (1973) studying chickens, a new « set-point » is established at that time, as Kennedy (1953) studying rats also showed. In traditional forced-feeding, the food intake augments up to the end of cramming, and the diet offered is different from the one used in our study.

This indicates that, as in the rat, the electrolytic destruction of the VMH disturbs some hormonal and metabolic systems (Frohman and Bernardis, 1968 ; Frohman *et al.*,

1969), thus favorizing fat depots in the liver and adipose tissue. Biochemical analyses are necessary to determine the variations in the blood constants of the treatment-related factors causing changes in adiposity.

Pancreas weight remained stable after treatment. However, in the rat Louis-Sylvestre, Ferlampin and Le Magnen (1972) showed that destruction of the VMH nuclei caused prandial and postprandial hyperinsulinemia which continued throughout the life of the animal. Nir *et al.* (1972) reported that the weight of the pancreas was unaffected by forced-feeding.

Knowing that different stress reactions cause adrenal hypertrophy in birds (Sturkie, 1965), would operated geese, which become apathetic and non-aggressive towards the observer, be less sensitive also to the cries of their congeners during manipulation? If so, it might explain the relatively significant reduction of their adrenal weights. On the contrary, however, it is also possible that ACTH secretion might be reduced (as shown for the somatotrophic hormone after VMH lesions) thus causing adrenal hypertrophy and reduced stress reaction.

Conclusion.

Some physiological analogies may be drawn between the rat and the goose. As in the rat and the chicken, destruction of the goose VMH intervenes in liveweight regulation by stimulating lipogenesis since the total amount of fat, but of no other tissue, increased considerably. As compared to forced-feeding, this development of subcutaneous fat was particularly significant. Moreover, neither metabolic and hormonal changes nor behavioral deviations resulting from VMH lesion affected fatty liver formation, which was insufficient for practical purposes.

In such a case, our data would indicate that the progress of hyperphagia with the premature appearance of the static phase, reducing food intake, seemed to have a negative effect. In fact, overeating continued over a longer period after 6-hydroxydopamine injection (Auffray and Gallouin, 1972; Auffray *et al.*, 1973), and higher weight fatty livers were obtained.

Our data tend to implicate the whole of the hyperphagic development (amplitude and duration) rather than insufficient digestive capacity or assimilation.

Résumé. Les effets de l'hyperphagie hypothalamique provoquée et du gavage ont été étudiés chez 30 oies de race landaise. Logées en cages individuelles, elles sont soumises à un cycle lumineux de 12 h de lumière, 12 h d'obscurité. 11 oies avec lésions ventromédianes hypothalamiques et 8 témoins reçoivent une alimentation *ad libitum* tandis que le 3^e lot comporte 11 animaux gavés en pair-feeding sur les opérés. L'étude porte sur une durée de 4 semaines après une période d'adaptation aux nouvelles conditions du milieu. La consommation journalière des oies ainsi que leur gain de poids hebdomadaire sont enregistrés. Après les lésions hypothalamiques VMH, la consommation moyenne des oiseaux augmente de 169 p. 100 de telle sorte qu'après chacun des traitements leur poids corporel s'est élevé et ils sont obèses ($p < 0,001$). Au niveau composition corporelle, le groupe lésé présente une plus grande quantité de graisse sous-cutanée ($p < 0,05$) tandis que la graisse mésentérique ($p < 0,05$) est plus abondante après gavage. Dans tous les cas le poids du foie est

fortement accru. L'augmentation relative atteint 193 p. 100 chez les oies avec lésions VMH et 123 p. 100 chez les gavées. Néanmoins, ces valeurs sont trop faibles lorsqu'on les compare aux moyennes obtenues lors du gavage traditionnel. L'hyperphagie obtenue chez l'oie est très marquée lorsqu'on la compare à celle du rat mais elle reste insuffisante dès qu'il s'agit de produire une stéatose hépatique importante.
