(Received 11 November 2002; accepted 26 February 2003)

Abstract — Seasonal changes in ovulatory activity, assessed by the measurement of plasma progesterone and plasma prolactin concentrations were monitored in 10 Spanish ibex females captured in the National Wildlife Reserve of Sierra Nevada (South Spain, 37° N). Five of the 10 female ibex showed ovulatory activity with a mean (\pm s.e.m.) duration of the oestrous cycle of 19.4 ± 1 days (range: 17–23 days). On average, the five cyclic females weighed 28 ± 0.9 kg. Progesterone cycles occurred only in animals older than 4 years of age. Ovulatory activity extended from December to January. The duration of the breeding season was 43.2 ± 7.7 days. Ibex females younger than 4 years of age had a body weight lower ($P < 0.01$) than that of adults and none of them displayed ovulations. Plasma concentrations of prolactin levels were significantly affected by season ($P < 0.05$), following a trend that was roughly parallel to daylength. The highest values occurred in the spring (119.7 ± 21.4 ng·mL⁻¹) and the summer (139.3 ± 19.8 ng·mL⁻¹), the lowest values in the autumn (26 ± 7.4 ng·mL⁻¹) and in the winter (19.7 ± 3.2 ng·mL⁻¹). Our results showed a very restricted breeding season, despite the fact that the Spanish ibex originates from and lives in a temperate latitude, revealing a remarkably good adaptation to the harsh climatic and nutritional conditions of their mountainous habitat.

breeding season / ovulation / progesterone

1. INTRODUCTION

The Spanish ibex (*Capra pyrenaica*) is a wild caprine originating exclusively in the

mountains of the Iberian Peninsula. Only two of the four original subspecies (*C. p. hispanica*, *C. p. victoriae*, *C. p. lusitanica*, *C. p. pyrenaica*) [1] still exist. *C. p. lusitanica* became extinct

* Corresponding author: moreno@inia.es

last century, and *C. p. pyrenaica* has recently and definitively disappeared. The Spanish ibex is currently considered as a vulnerable species [2] because of the loss of heterozygosity by inbreeding in small isolated populations formed by habitat fragmentation, and because of low food availability in high density populations. This fragmentation of the population leads to a loss of natural population control mechanisms and increases the risks associated with inbreeding, such as unmasking of deleterious recessive genes, fertility problems and a decreased function of the immune system [3]. In this regard, studies on reproduction in the Spanish ibex are highly relevant to the preservation of genetic resources in wildlife. A good knowledge of their reproductive physiology is therefore a prerequisite for a successful use of methods of assisted reproduction, widely used in domestic animals (gamete cryopreservation, artificial insemination, embryo transfer and in vitro fertilisation) [4, 5]. They allow dispersion of the existing gene pools with minimal transport of animals and the introduction of new genes from wild populations into captive breeding programmes, counteracting a possible risk of extinction in one specific Spanish ibex population.

The second major point of interest is related to the use of the Spanish ibex as a valuable animal model to study environmental influences on seasonal breeding activity and endocrine response. Prolactin secretion is increased or decreased in response to variation in photoperiod in all photoperiodic mammals studied so far, with the highest and lowest concentrations occurring during the summer and winter, respectively [6]. Among other functions, prolactin has also been implicated in regulating gonadal activity and sexual behaviour [7, 8]. The temporal pattern of reproductive activity in many mammalian species is affected by the geographic origin (latitude). In the mountains of northern Ethiopia (10° N latitude), the Walia ibex (*Capra walie*) is distinguished from other ibex species in its ability to breed at all times of the year, although most often

the Walia Ibex mates during the rut season, from February until June [9, 10]. In contrast, at high latitudes (45° N), the Alpine ibex (*Capra ibex ibex*) shows a mating season restricted to December [11]. Although the Spanish ibex originates and lives in a moderate latitude (37° N), field observations have shown that the period of the rut is very short (December-January) in many wild populations [12]. A wide range of variation in the length of the sexual active phase has, however, been observed between populations of the Spanish ibex located in neighbouring areas but with very differentiated climatic characteristics [13]. Considering that previous reports have described differences in the extension of the breeding season in wild species when behavioural methods and other precise analytical methods are compared [14], analytical methods to accurately assess the seasonal ovulatory cycle of the Spanish ibex are required.

The present work was conducted to characterise the seasonal ovulatory activity in the Spanish ibex, by measuring progesterone concentrations in peripheral blood, and to determine seasonal changes in plasma prolactin.

2. MATERIALS AND METHODS

2.1. Experimental design and animals

In July 1999, ten Spanish ibex females (*Capra pyrenaica hispanica*), aged 3 months to 7 years, were captured in a National Wildlife Park (Sierra Nevada, Southeastern Spain; 36° 55'–37° 10' N, 2° 34'–3° 40' W). The animals were transferred to the Animal Reproduction Department, INIA (Madrid; 40° 25' N, 3° 68' W), and housed in two sand-floor stables (250 m²) adapted for maintenance of the ibex, with a partial roof cover, under natural photoperiod. To alleviate stress during the experimental procedures, an acclimatisation period to routine restraints

and handling, of at least 6 months, was allowed before the beginning of the experiment. During this period, animals were accustomed to going into a small stall to allow blood collection. In addition, during manipulations the eyes of the animals were covered with a mask. The ibex age was assessed by their teeth (replacement of deciduous teeth) and horns (marks of growth) [15]. At the onset of the experiment (October 2000) the female ibexes were 1.5–8 years of age and were classified into three classes [16]: yearling (1.5 years of age, $n = 2$); sub-adult (2–4 years of age, $n = 3$); adult (> 4 years of age, $n = 5$). Total replacement of deciduous teeth and full physical development (body weight and horn growth) is only reached in the adult class (mean adult weight: 31 kg) [15, 17]. The ibexes were fed a balanced diet consisting of barley grain, barley straw, and dry alfalfa. The animals had free access to water and mineral blocks containing minerals and vitamins. All animals maintained a good health condition throughout the experimental period.

The animals were weighed once in December, coinciding with the period of sexual activity in the wild conditions [13].

2.2. Hormone assay

Blood samples were collected twice weekly for 13 months, by jugular venepuncture and centrifuged at 1 500 g for 15 min. The plasma was separated and stored at -15°C until progesterone and prolactin analyses were performed.

Progesterone determinations were performed in duplicate 200 μL aliquots of plasma by radioimmunoassay (RIA) according to the procedure developed by Lopez-Sebastian et al. [18]. The inter- and intra-assay coefficients of variation were 13.6% ($n = 6$) and 10.4% ($n = 8$) respectively, and the limit of detection of the assay was $0.16 \text{ ng}\cdot\text{mL}^{-1}$. The mean extraction efficiency was $84.3 \pm 3.2\%$ ($n = 10$).

The prolactin analysis was performed only in two of the samples recovered each month (two weeks apart). Plasma concentrations of prolactin were determined by RIA in duplicate 100 μL aliquots by a previously described method [19]. All samples were analysed in a single assay. The limit of detection of the assay was $0.2 \text{ ng}\cdot\text{mL}^{-1}$ and the intra-assay coefficient of variation was 9.3% ($n = 8$).

2.3. Analysis

The date of onset of ovarian activity was taken as the date before progesterone rose above $0.5 \text{ ng}\cdot\text{mL}^{-1}$ in two consecutive plasma samples [20]. The date of the end of ovarian activity was the first sample date with progesterone concentrations lower than $0.5 \text{ ng}\cdot\text{mL}^{-1}$ followed by basal levels in successive plasma samples. The effect of age on the establishment of ovulatory activity was analysed by ANOVA. In order to perform this analysis, yearling and sub-adult animals were pooled, considering only two groups of age (older and younger than 4 years old). The times of the peak and nadir (basal level) of the annual cycle in the concentration of prolactin was calculated for each animal using a three-point moving average [6]. This involved calculating the mean value for each three consecutive time points and repeating this throughout the year to determine the time of the maximum or minimum value for each animal. The timing of the increase and attainment of the basal level in prolactin were determined using a graph of the accumulated sums of the plasma concentrations of prolactin for each animal. Lines were fitted to the main slopes of the graph. The intercepts related to the x axis gave the time of the increase and attainment of the basal level in prolactin [21]. Prolactin concentrations had a skewed distribution and were therefore log-transformed before analysis. The effect of the season on the mean circulating levels of prolactin was assessed by one way

repeated-measures ANOVA. Differences in body weight were analysed by a *t*-test. The results are presented as mean \pm s.e.m. All statistical procedures were performed with the BMDP, Statistical Software, Inc.

3. RESULTS

Five of the 10 female ibex showed ovulatory activity (Fig. 1) with 1 to 3 progesterone cycles (peaks of 1.4 ± 0.1 ng·mL⁻¹). The mean duration (\pm s.e.m) of the oestrous cycle was 19.4 ± 1 days (range: 17–23 days). Two females showed 1 short cycle of progesterone (10–14 days and average maximum values of 0.8 ± 0.2 ng·mL⁻¹) prior or following a cycle of normal duration. A sixth female (3.5 years of age) showed only a short cycle (12 days) with a peak of 1.2 ng·mL⁻¹ of progesterone. This animal was not included in the females with ovarian activity because this cycle was not followed by any cycle of normal duration. The other 4 females did not show any ovulatory cycle. The first cycle of progesterone appeared between 3 and 27 December (mean \pm s.e.m: December 16 ± 5 days). The end of the seasonal ovulatory activity stretched from 15 January to 9 February (January 29 ± 4 days). The duration of the breeding season was 43.2 ± 7.7 days.

Figure 1. Cyclical ovarian activity in 5 Spanish ibex females, determined by progesterone concentrations in blood samples collected twice weekly.

Figure 2. Changes in plasma concentrations of prolactin (mean \pm s.e.m.) throughout the year in Spanish ibex females ($n = 10$). (Blood samples collected twice monthly).

ANOVA revealed an influence of age ($P < 0.001$) on the establishment of ovulatory activity. Initial progesterone increases occurred only in animals older than 4 years of age (adults, $n = 5$). On average, adult females weighed 28 ± 0.9 kg. Ibex females younger than 4 years of age did not display ovarian activity ($n = 4$) or showed only a short ovarian cycle ($n = 1$). The body weights (mean \pm s.e.m) in both yearling (17.4 ± 0.03 kg) and sub-adult (22.5 ± 1.6 kg) animals were lower than that of the adult ones ($P < 0.01$).

The profile of prolactin concentrations followed a trend that was roughly parallel to daylength (Fig. 2). The timing of the increase in prolactin concentrations and attainment of basal levels were April and October, respectively. Mean (\pm s.e.m) circulating levels were significantly affected by season ($P < 0.05$). The highest values occurred in the spring (119.7 ± 21.4 ng·mL⁻¹) and summer (139.3 ± 19.8 ng·mL⁻¹), and the lowest ones in the autumn (26 ± 7.4 ng·mL⁻¹) and in the winter (19.7 ± 3.2 ng·mL⁻¹).

4. DISCUSSION

The results of this study showed that adult female ibexes maintained under captive conditions displayed a period of ovulatory activity from December to January, followed by a long anoestrous period. The progesterone profiles revealed an oestrous cycle length similar to the cycle length of the domestic goat [22]. Our results revealed a high proportion of females with short cycles, which seems to be a characteristic of the caprine species and breeds [23–25], as well as females showing only one cycle of variable duration. It is unknown if these findings are usual in the wild. Ovulatory activity could be affected by captive conditions and isolation from males. In domestic goats, the sudden introduction of males affects the duration of the oestrous cycle [26]. In feral goats of Australia, the absence of males shortens the duration of ovulatory

activity by about two months, by changing both the onset and the offset of the sexual activity [27]. The role of different social cues, such as the presence of a male, in the regulation of the ovulatory cyclicity and timing of seasonal anoestrous of the Spanish ibex is unknown and remains to be tested. However, this species exhibits a rich behavioural pattern in the wild, with complete sexual segregation outside the rut [13]. We thus assume that the buck's odour, physical contact and ritual behaviour are important factors in the control and duration of ovulatory activity.

It is not clear whether or not stress caused by captive conditions and blood recovery procedures could have affected our findings. In this regard, mouflons maintained at similar environmental conditions have a higher number of ovarian cycles (mean 10 cycles) of normal duration [14] than that detected in the ibex of the current study. Most investigators who have examined the role of stress in ovulatory activity have considered that stress appears to delay or abolish ovulation in some females [28, 29]. Specifically, stress reduces the normal pulsatile patterns of GnRH and, consequently, suppresses or delays the surge of LH [30, 31]. The absence of ovulation in about half of the females might be explained, at least in part, by the wide between-individual range of variability in response to stressful conditions of captivity. However, cycles were not detected in females younger than 4 years old, suggesting that other factors might also account for the absence of cycles. The results suggest that ovulatory activity could be related to body weight. In our experimental conditions, the mean weight reached by the cycling ibex was about 28 ± 0.9 kg, which is close to the body weight previously established in adult females living in Sierra Nevada [17]. In contrast, field observations suggest that female Spanish ibexes do not mate until 2.5 years of age, when they reach a body weight higher than 24 kg [32, 33]. The lack of ovulation could therefore be associated

with stress and liveweight, which may be related to the social status of the females in captive conditions. Previous studies in red deer (*Cervus elaphus*) suggest that corpus luteum function is affected by social status [34]. In rodents and monkeys, it has been demonstrated that only dominant females ovulate and inhibit the ovulation in subordinated females through aggression, visual cues and pheromones [35, 36]. In ibexes raised in captivity, the social interactions are reinforced and aggression directed towards dominated females (usually with lower bodyweight) has been frequently observed in our study. Specifically, the adult ibex with the highest aggressive behaviour towards other females showed a larger number of cycles (see ibex 570 in Fig. 1). Although reproductive suppression in the ibex raised in captivity could be under the control of the dominant breeder, we have not tested the individual level of dominance and subordination in all the females and furthermore studies are therefore needed to test this hypothesis.

Our results reveal a marked seasonality of reproduction, despite the fact that the ibexes originate and live in a temperate latitude. Ovulatory activity extends from December to January, which is in agreement with the timing of the rut period reported in field for ibexes living in the Sierra Nevada National Park [12]. In addition, the breeding season is similar to other ibex species originating from and living in higher latitudes, such as the Alpine ibex maintained both in wild [37] and captive conditions [38]. However, the ovulatory activity period was shorter than the mating season reported in wild or captive populations of the Spanish ibex living in other geographical areas of the Iberian Peninsula [15, 39]. This period was also shorter than that of other wild ruminant species living in the Iberian Peninsula at a similar or higher latitude [14]. Whether these differences are determined by a variable sensitivity to the photoperiod is not known. However, variations in photoperiodic response are seen not only between species

but also between breeding populations within a species [40]. A higher sensitivity to the short photoperiod in the Spanish ibex from Sierra Nevada in relation with other populations may explain this variability in the length of the sexual active phase.

To our knowledge, no study has characterised the annual profile of prolactin secretion in the different species of the ibex. Photoperiod has been identified as the main environmental factor regulating the seasonal secretion of prolactin in many domestic and wild species adapted to cold and temperate climates [6, 41]. Furthermore heat stress may increase prolactin secretion [42]. The present study also revealed that plasma prolactin concentrations in the Spanish ibex were high during long days and low during short days. Basal levels were observed in October, similarly to domestic goats [43] and other wild species under the same environmental conditions, such as the mouflon [44]. However the timing of the increase in prolactin concentrations, in April, occurred three months later than in wild sheep and one month later than in domestic goats [43]. Genetic differences in response to photoperiodic changes may also explain this difference.

In conclusion, this study showed a very restricted breeding season, despite the fact that the Spanish Ibex originates and lives under a temperate latitude, revealing a remarkably good adaptation to the harsh climatic and nutritional conditions of their mountainous habitat. The data support the existence of a substantial influence of the age and body weight on the establishment of the ovulatory activity under captivity conditions, which should be taken into account in captive breeding programmes.

ACKNOWLEDGEMENTS

We express our gratitude to the National Wildlife Park of Sierra Nevada (Granada, Spain) for the generous provision of ibexes. This work was supported by CICYT grants AGL2000-

1375, AGL2001-0335. JSM and AGB were supported by the Ramón y Cajal Research Programme from the Spanish Ministry of Science and Technology.
